Gas hydrates consist of molecules of natural gas (the chief constituent of natural gas; methane) enclosed within a solid lattice of water molecules. When brought to the earth's surface, one cubic meter of gas hydrate releases 164 cubic meters of natural gas.

Unlike the ice we're all familiar with that's derived entirely from water, gas hydrates are in fact highly flammable, a property that makes these crystalline structures both an attractive future energy source as well as a potential hazard. Hydrates are a much more abundant source of natural gas than conventional deposits. According to the U.S. Geological Survey, global stocks of gas hydrates range account for at least 10 times the supply of conventional natural gas deposits, with between ...

This research is important because methane hydrate deposits are believed to be a larger hydrocarbon resource than all of the world's oil, natural gas and coal resources combined. If these deposits can be efficiently and economically developed, methane hydrate could become the next energy game changer.

Methane Hydrate: The World's Largest Natural Gas Resource

Accurately quantifying the amount of naturally occurring gas hydrate in marine and permafrost environments is important for assessing its resource potential and understanding the role of gas hydrate in the global carbon cycle. Electrical resistivity well logs are often used to calculate gas hydrate saturations, S_h , using Archie's equation.

Gas hydrates (or clathrate hydrates) are ice-like crystalline molecular complexes formed from mixtures of water and suitably sized 'guest' gas molecules. The water (host) molecules, upon hydrogen bonding, form lattice structures with several interstitial cavities.

In the 1960's it was recognized that considerable quantities of gas hydrate, namely methane hydrate, occur naturally in sediments of the subsea continental slopes, and in the subsurface of Arctic permafrost regions. Figure-2 shows a sediment sample retrieved from the seafloor which contains layers of gas hydrates.
